### **Abstract**

Long-term PM<sub>2.5</sub> exposure has been reported to be associated with various adverse health outcomes. However, most ground monitors are located in urban areas, leading to a potentially biased representation of the true regional PM<sub>2.5</sub> levels. To facilitate epidemiological studies, accurate estimates of spatiotemporally continuous distribution of PM<sub>2.5</sub> concentrations are essential. Satellite-retrieved aerosol optical depth (AOD) has been widely used for PM<sub>2.5</sub> concentration estimation due to its comprehensive spatial coverage. Nevertheless, an inherent disadvantage of current AOD products is their coarse spatial resolutions. For instance, the spatial resolutions of the Moderate Resolution Imaging Spectroradiometer (MODIS) and the Multiangle Imaging Spectro-Radiometer (MISR) are 10 km and 17.6 km, respectively. In this paper, a new AOD product with 1 km spatial resolution retrieved by the multi-angle implementation of atmospheric correction (MAIAC) algorithm was used. A two-stage model was developed to account for both spatial and temporal variability in the PM<sub>2.5</sub>-AOD relationship by incorporating the MAIAC AOD, meteorological fields, and land use variables as predictors. Our study area is in the southeastern US, centered at the Atlanta Metro area, and data from 2001 to 2010 were collected from various sources. The model was fitted for each year individually, and we obtained model fitting  $R^2$  ranging from 0.71 to 0.85, MPE from 1.73 to 2.50  $\mu$ g m<sup>-3</sup>, and RMSPE from 2.75 to 4.10  $\mu$ g m<sup>-3</sup>. In addition, we found cross validation  $R^2$  ranging from 0.62 to 0.78, MPE from 2.00 to 3.01  $\mu$ g m<sup>-3</sup>, and RM-SPE from 3.12 to 5.00 µg m<sup>-3</sup>, indicating a good agreement between the estimated and observed values. Spatial trends show that high PM<sub>2.5</sub> levels occurred in urban areas and along major highways, while low concentrations appeared in rural or mountainous areas. A time series analysis was conducted to examine temporal trends of PM<sub>2.5</sub> concentrations in the study area from 2001 to 2010. The results showed that the PM<sub>2.5</sub> levels in the study area followed a generally declining trend from 2001 to 2010 and decreased about 20 % during the period. However, there was an exception of an increase in year 2005, which is attributed to elevated sulfate concentrations in the study area in

10 yr trend of PM<sub>2.5</sub> concentrations in the southeastern US

### 1 Introduction

Long-term exposure to PM<sub>2.5</sub> (particle size less than 2.5 µm in the aerodynamic di-5 ameter) is associated with various adverse health outcomes including respiratory and cardiovascular diseases (Crouse et al., 2012; Peng et al., 2009). Due to the spatiotemporally continuous nature of fine particles, obtaining long-term and spatially-resolved distribution of PM<sub>2.5</sub> concentrations is important to reduce exposure misclassification and facilitate accurate epidemiological studies in the region. In addition, time series analyses of air pollution and human health have become the most common study design to compare day-to-day fluctuations of air pollution and corresponding fluctuations in health outcomes (Ito et al., 2007), requiring long-term PM<sub>2.5</sub> concentration estimates. Previous research examined temporal trends in PM<sub>2.5</sub> levels. For instance, Weber et al. (2003) investigated the temporal variations in PM<sub>2.5</sub> mass at the US Environmental Protection Agency (EPA) Atlanta Supersite Experiment in August 1999. So et al. (2007) examined long-term variation in PM<sub>2.5</sub> levels during two 12 month periods in Hong Kong. EPA (2011) reported temporal trends of annual and 24 h mean PM<sub>2.5</sub> concentrations at the national level from 2001 to 2010 and found that annual and 24 h mean  $PM_{2,5}$  concentrations dropped 24 % and 28 %, respectively, within these ten 20 years.

Another critical aspect is the investigation of spatial trends of PM<sub>2.5</sub> levels. Stationary ambient monitors have been established to measure ground-level PM<sub>2.5</sub> concentrations, yet those point measurements leave large areas uncovered, and therefore spatial variability is difficult to assess with those point measurements alone. In addition, these sites do not measure individual-specific exposure, and thus this approach inevitably introduce measurement errors that likely have substantial implications for interpreting epidemiological studies, especially for time-series analyses (Zeger et al., 2000).

10 yr trend of PM<sub>2.5</sub> concentrations in the southeastern US

The objective of this paper is first, to estimate spatiotemporally-resolved PM<sub>2.5</sub> concentrations in the study domain during the period between 2001 and 2010 using a two-stage model with MAIAC AOD as the primary predictor and meteorological and land use variables as the secondary predictors. Second, maps of annual mean PM<sub>2.5</sub> concentrations as well as the changes between 2001 and 2010 were generated from the daily estimates to visually illustrate spatial trends of annual PM<sub>2.5</sub> levels from 2001 to 2010. Third, time series analyses were conducted for the study domain and the Atlanta metro area using the monthly and annual mean PM<sub>2.5</sub> estimates to examine the 10 yr temporal trends of fine particle levels, and the underlying causes were discussed. Finally, potential impact of wild and prescribed fires on PM<sub>2.5</sub> levels in the south of our study region was investigated.

### 2 Materials and methods

### 2.1 Study area

The study area is approximately 600 × 600 km<sup>2</sup> in the southeastern US, covering most of Georgia, Alabama, and Tennessee, and parts of North and South Carolina (Fig. 1).

X. Hu et al.

### 10 2.2 PM<sub>2.5</sub> measurements

The 24h average  $PM_{2.5}$  concentrations from 2001 to 2010 collected from US Environmental Protection Agency (EPA) federal reference monitors (FRM) were downloaded from the EPA's Air Quality System Technology Transfer Network (http://www.epa.gov/ttn/airs/airsaqs/).  $PM_{2.5}$  concentrations less than  $2 \, \mu g \, m^{-3}$  (~0.2–3% of total data records) were discarded as they are below the established limit of detection (EPA, 2008a).

### 2.3 Remote sensing data

MAIAC retrieves aerosol parameters over land at 1 km resolution, which was accomplished by using the time series of MODIS measurements and simultaneous processing of a group of pixels in fixed 25 × 25 km² blocks (Lyapustin et al., 2011a, b, 2012). MAIAC uses a sliding window to collect up to 16 days of MODIS radiance observations over the same area and processes them to obtain surface parameters used for aerosol retrievals. To facilitate the time series analysis, MODIS data are initially gridded to a 1 km resolution in a selected projection. For this work, we used MODIS level 1B (calibrated and geometrically corrected) data from Collection 6 re-processing, which

Interactive Discussion

Validation showed that the MAIAC and operational Collection 5 MODIS Dark Target AOD have a similar accuracy over dark and vegetated surfaces, but also showed that MAIAC generally improves accuracy over brighter surfaces, including most urban areas (Lyapustin et al., 2011b). MAIAC AOD data from 2001 to 2010 were obtained from NASA Goddard Space Flight Center.

Zhang et al. (2012) found that Terra and Aqua may provide a good estimate of the daily average of AOD, thus the average of Aqua and Terra measurements can be used to predict PM<sub>2.5</sub> concentrations. In this study, Aqua (overpass at ~1:30 p.m. LT) and Terra (overpass at ~10:30 a.m. LT) MAIAC AOD values were first combined to improve spatial coverage. In a common MAIAC pixel, there might be only one MAIAC product from either Aqua or Terra, or both may be present. In the second case, when we combine them, the averaged value represents the mean of the AOD distribution from 15 10 a.m. to 2 p.m. LT, yet in the first case, AOD as an indicator of PM<sub>2.5</sub> abundance is biased towards the atmospheric condition either in the morning or early afternoon. To overcome this bias, Lee et al. (2011) defined a simple ratio between averaged Terra and Aqua AOD to estimate the missing AOD value. In this study, we fitted a linear regression to define the relationship between daily mean AOD values of MAIAC-Terra and 20 MAIAC-Aqua. We used this regression to predict the missing AOD value (i.e., predict MAIAC-Terra AOD with the available MAIAC-Aqua AOD, and vice versa), then averaged the observed and the predicted AOD values together. Finally, we set an upper bound of 2.0 for the combined AOD to reduce potential cloud contamination (~0.05-0.1 % of total data records were excluded).

The fire detection data for the study region were obtained (USDA) Serfrom the US Department Agriculture Forest Remote Sensing Applications 2001 2010 vice's Center for through (http://activefiremaps.fs.fed.us/gisdata.php?sensor=modis&extent=north america). ACPD

### 2.4 Meteorological fields

The meteorological fields provided by the North American Land Data Assimilation System (NLDAS) Phase 2 were downloaded from the NLDAS website (http://ldas.gsfc.nasa.gov/nldas/). The spatial resolution of NLDAS meteorological data is 1/8th-degree (~13 km). Another meteorological dataset used in this study is the North American Regional Reanalysis (NARR). NARR is a long term, consistent, high-resolution climate dataset for North America (Mesinger et al., 2006). The spatial resolution of the NARR dataset is ~32 km. NLDAS provides most of the meteorological fields used in this analysis, including relative humidity, u-wind, and v-wind, while NARR provides another critical parameter: boundary layer height. To generate daytime meteorological fields corresponding to the MODIS overpass times, 3-hourly NARR measurements and hourly NLDAS measurements from 10 a.m. to 4 p.m. standard local time were averaged.

### 2.5 Land use variables

Elevation data were downloaded from the national elevation dataset (NED) (http://ned.usgs.gov). NED is the seamless elevation dataset covering the conterminous United States and is distributed by the US Geological Survey (USGS). The elevation data are downloaded at a spatial resolution of 1 arcsec (~30 m). The road data were obtained from ESRI StreetMap USA (Environmental Systems Research Institute, Inc., Redland, CA). The road data at level A1 (limited access highway) were extracted. Summed length of road segments were calculated for each 1 × 1 km² MAIAC grid cell, and grid cells with no roads were assigned zero. 2001 and 2006 Landsat-derived land cover maps covering the study area with a spatial resolution of 30 m were downloaded from the National Land Cover Database (NLCD) (http://www.epa.gov/mrlc/nlcd-

### Data integration 2.6

All the data were first re-projected to the USA Contiguous Albers Equal Area Conic USGS coordinate system. For model fitting, a 1 x 1 km<sup>2</sup> square buffer was generated for each PM<sub>2.5</sub> monitor site. Meteorological fields and AOD values were assigned to each 10 PM<sub>2.5</sub> monitor site using the nearest neighbor approach. Forest cover and elevation were averaged, while road length and point emissions were summed over the 1 x 1 km<sup>2</sup> square buffer. For  $PM_{2.5}$  prediction, the same procedure was performed for each 1  $\times$ 1 km<sup>2</sup> MAIAC grid cell.

### 2.7 **Model structure**

15 We developed a two-stage spatiotemporal model. The first stage is a linear mixed effects model with day-specific random intercepts and slopes for AOD, meteorological fields to account for the temporally varying relationship between PM25 and AOD (Eq. 1). The model structure can be expressed as

$$\begin{split} \mathsf{PM}_{2.5,st} &= (b_0 + b_{0,t}) + (b_1 + b_{1,t}) \mathsf{AOD}_{st} + (b_2 + b_{2,t}) \mathsf{Meteorological Fields}_{st} \\ &\quad + b_3 \mathsf{Elevation}_s + b_4 \mathsf{Major Roads}_s + b_5 \mathsf{Forest Cover}_s \\ &\quad + b_6 \mathsf{Point Emissions}_s + \varepsilon_{st}(b_{0,t}b_{1,t}b_{2,t}) \sim \mathit{N}[(0,0,0), \Psi] \end{split} \tag{1}$$

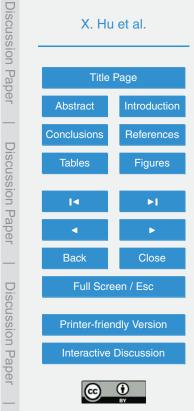

where  $b_i$  and  $b_{i,t}$  (day-specific) are the fixed and random intercept and slopes, respectively;  $PM_{2.5,st}$  is the measured ground level  $PM_{2.5}$  concentration ( $\mu g m^{-3}$ ) at site s in day t; AOD<sub>st</sub> is the MAIAC AOD value (unitless) at site s in day t; Meteorologi-25625

### **ACPD**

Discussion Paper

13, 25617-25648, 2013

10 yr trend of PM<sub>2.5</sub> concentrations in the southeastern US

The second stage is a geographically weighted regression (GWR) model that can generate a continuous surface of estimates for each parameter at each location instead of a universal value for all observations. We fitted a monthly GWR model to calibrate the spatial variability within the  $PM_{2.5}$ -AOD relationship, and the model can be expressed as

$$PM_{2.5} - resi_{st} = \beta_{0.s} + \beta_{1.s} AOD_{st} + \varepsilon_{st}$$
 (2)

where  $PM_{2.5}$ \_resi<sub>st</sub> denotes the residuals from the stage one model at site s in month t, AOD<sub>st</sub> is the MAIAC AOD value (unitless) at site s in month t, and  $\beta_{0,s}$  and  $\beta_{1,s}$  denote the location-specific intercept and slope, respectively.

It should be noted that the model was fitted for each year individually, and therefore the predictors used in the model may vary for different years. The model structures were determined by comparison of performance of models using different predictors to ensure that relatively better prediction accuracy can be achieved. To assess the goodness of fit of the model, various statistical indicators such as the coefficient of determination  $(R^2)$ , mean prediction error (MPE), and square root of the mean squared 25626

### 5 3.2 Results of model-fitting and validation

The model-fitting and CV statistics (e.g.  $R^2$ , MPE, and RMSPE) are listed in Table 2. The results show that  $R^2$  ranges from 0.71 to 0.85, MPE is from 1.73 to 2.50  $\mu$ g m<sup>-3</sup>, RMSPE ranges from 2.75 to 4.10  $\mu$ g m<sup>-3</sup>, and relative accuracy ranges from 72.9% to 80.7%, which indicate a good fit between predicted values from the fitted models and the observations. In addition, CV statistics results suggest that model over-fitting is present; that is,  $R^2$  decreases, while MPE and RMSPE increase from model fitting to cross validation, yet the differences are relatively small for all the years. For instance,  $R^2$  and relative accuracy have an average decrease of 0.08 and 4.21%, respectively, while MPE and RMSPE have an average increase of 0.39 and 0.60  $\mu$ g m<sup>-3</sup>, respectively through all the years. Moreover, a regression with zero intercept (Fig. 2) was performed to fit the predicted values against the observations. The figure shows that at high concentration levels, both model fitting and cross validation under-predicted the PM<sub>2.5</sub> concentrations by 3–7% (e.g. fitted/CV PM<sub>2.5</sub> = 97% to 93% observed PM<sub>2.5</sub>).

### 3.3 Spatial trends of PM<sub>2.5</sub> concentrations

Figure 3 illustrates the  $PM_{2.5}$  concentration estimates at 1 km spatial resolution in the study area. The annual mean estimated concentrations are 13.97, 13.90, 13.35, 13.31, 15.19, 13.73, 13.22, 11.34, 10.58, and 11.22  $\mu$ gm<sup>-3</sup> for year 2001 though 2010, respectively. The patterns of  $PM_{2.5}$  distribution are very similar for all the years. High concentrations appear in large urban centers and along major highways, while low concentrations occur in rural and mountainous areas. In addition, high  $PM_{2.5}$  levels also occur in the south of the study domain. This area is primarily occupied by agriculture

Interactive Discussion

land, and high agricultural emissions may lead to high concentrations of fine particles. As reported by previous studies, ammonia (NH<sub>3</sub>) and nitrogen oxides (NO<sub>x</sub>) generated by agricultural activities, such as farm vehicles, domestic and farm animals, and fertilizer applications, can significantly increase the number of suspended particles (Kurvits 5 and Marta, 1998). In addition, biomass burning also contributes to emissions of fine particles in the region (Zhang et al., 2010). Figure 4 shows that the pattern of ground PM<sub>2.5</sub> measurements from FRM monitors corresponds well with that of our estimated concentrations.

To take advantage of the high spatial resolution of the MAIAC data, a map of PM<sub>2.5</sub> estimates in Atlanta metro area was also generated for each year (Fig. 5). The annual mean estimates from 2001 to 2010 are 15.10, 14.64, 14.00, 14.54, 15.63, 14.39, 14.14, 11.78, 10.98, and 11.65 µg m<sup>-3</sup>, respectively. Those maps distinctly show that high PM<sub>2.5</sub> levels occur in areas with high urban land use and along major highways, while low concentrations appear in forest and recreational areas, suggesting an underlying positive relationship between air pollution levels and urban development.

Figure 6 shows the percent changes in PM<sub>2.5</sub> concentrations from 2001 to 2010. Figure 6a illustrates the spatial trend of changes in PM<sub>2.5</sub> levels in the study region. The results show that PM<sub>2.5</sub> levels in most of the areas decreased from 0 to 25 %, and large parts of the areas had decreases exceeding 25% and up to 50%. Larger decreases 20 occurred in areas with generally higher pollution levels such as Atlanta metro area and along major highways, which might be due to recently enacted emission reduction program (EPA, 2011), since majority of the emission sources are located in or near urban areas and along major highways. Mitigation of fine particles has been effected through control of direct PM<sub>2.5</sub> emissions from both stationary and mobile sources 25 (e.g., through installation of scrubbers and filters and the use of alternative fuels and electric vehicles) (EPA, 2007). One exception is the mountainous area in the northeast of our domain with generally low PM<sub>2.5</sub> levels. The decreases of PM<sub>2.5</sub> concentrations in this region from 2001 to 2010 were also phenomenal, PM<sub>2.5</sub> levels decreased from 25 % to 50 % in most of the region, and some areas had decreases exceeding 50 %.

### **ACPD**

13, 25617-25648, 2013

10 yr trend of PM<sub>2.5</sub> concentrations in the southeastern US

### 3.4 Temporal trends of PM<sub>2.5</sub> concentrations

A time series analysis was conducted to quantitatively examine temporal trends of  $PM_{2.5}$  levels in the study area as well as the Atlanta metro area during the period between 2001 and 2010 (Fig. 7). The results show that the estimated  $PM_{2.5}$  concentrations are smaller than the monitored observations, and underestimation by our model has occurred, especially in areas with high pollution levels (e.g., the Atlanta metro area), which agrees with our model validation results. The average underestimation is  $0.99\,\mu g\,m^{-3}$  for the study domain and  $1.82\,\mu g\,m^{-3}$  for the Atlanta metro area. The  $PM_{2.5}$  levels in the study region as well as the Atlanta metro area followed a generally declining trend, especially after year 2005. From 2001 to 2010, the annual mean  $PM_{2.5}$  concentration decreased about 20 % in the study area and 23 % in the Atlanta metro area, which is in line with the findings documented in the US EPA report on particle pollution (EPA, 2011). Both EPA's and our results illustrate a peak of  $PM_{2.5}$  levels in

10 yr trend of PM<sub>2.5</sub> concentrations in the southeastern US

### 3.5 The impact of wild and prescribed fires on PM<sub>2.5</sub> concentrations

Zeng et al. (2008) suggested that prescribed fire emissions can result in a daily increase of  $PM_{2.5}$  mass up to  $25 \,\mu g \, m^{-3}$ , indicating high impact of fires on  $PM_{2.5}$  levels. Figure 8 illustrates the seasonal distribution of the number of fires in the study region. which shows that most wild and prescribed fires occurred in spring and fall, and the highest number of fires appeared in spring 2007. To assess the impact of fires on PM<sub>2.5</sub> levels, we selected year 2007 to conduct a case study as fires in the southeastern US in 2007 has been examined by previous research using ground monitoring data (Zhang et al., 2010). The differences of number of fires and annual mean PM<sub>2.5</sub> concentrations between two test sites were calculated and illustrated in Fig. 9. It shows that in most of the cases, the peaks and valleys of the differences of number of fires correspond well with the peaks and valleys of the differences of PM<sub>2.5</sub> concentrations (indicated by black arrows), indicating an underlying positive relationship between fires and PM<sub>2.5</sub> concentrations and suggesting that the fires may have impact on fine particle levels in the south of our study region. However, exceptions exist. For example, in April 2007, a day in which a large difference of number of fires occurred did not show a higher difference of PM<sub>2.5</sub> concentrations than its neighboring days. In addition, in many days in which there are no differences of number of fires, the differences of PM<sub>2.5</sub> concentrations between two test sites still exist. Such situations might be attributed to several 25 factors: first, due to the lack of data, our analysis only used the number of fires without fire scale and intensity information and thus might be biased. Second, although the contributions of fires to PM<sub>2.5</sub> levels are quite significant (~13 % annually) and vary by seasons in the southeastern US, fires might not be major drivers and there are other,

10 yr trend of PM<sub>2.5</sub> concentrations in the southeastern US

### 4 Discussion

A major strength of this study is that we used 1 km spatial resolution PM<sub>2.5</sub> estimates 5 derived from 1 km resolution MAIAC AOD to investigate spatiotemporal trends of PM<sub>2.5</sub> concentrations in the study area as well as in the Atlanta metro area. PM<sub>2.5</sub> estimates at finer resolutions are more suitable for investigation of spatial trends than those at coarser resolutions derived from other AOD products (e.g., MODIS and MISR), because estimates at coarser scales inevitably omit local spatial details. Our results are capable of showing PM<sub>2.5</sub> concentrations and changes within a 1 × 1 km<sup>2</sup> area, which are very useful for air pollution studies at local scales. For instance, spatial trends of changes in PM<sub>2.5</sub> concentrations in the Atlanta metro area show distinct patterns of higher PM<sub>2.5</sub> reduction in areas with generally higher pollution levels (e.g., urban builtup areas and along major highways). Some of the changes may be directly associated with the occurrence or disappearance of one or more emission sources as well as the increase or decrease of emissions from those sources. Although high resolution PM<sub>2.5</sub> estimates can provide more details to examine spatial trends, difficulties lie in validation to ground monitoring. More ground measurements at specific locations are needed to further validate the results.

Our results of temporal trends of PM<sub>2.5</sub> concentrations correspond well with EPA's results (EPA, 2011). However, results also show that our predicted PM<sub>2.5</sub> concentrations underestimated the ground measurements for almost all the years, which is expected. Most of the EPA FRM monitors are located in or near urban areas with generally high PM<sub>2.5</sub> levels. On the other hand, the temporal trends of PM<sub>2.5</sub> concentrations estimated from satellite AOD include the entire study domain and account for both urban and rural estimates, and therefore might more thoroughly represent the true fluctuations of

Interactive Discussion

In addition, long-term PM<sub>2.5</sub> estimates at high spatial resolutions might be better suited for incorporating fire data in order to examine the impact of fires on fine particle levels, since fires might occur far away from ground monitors. Our results show that fires, to some extent, contribute to PM<sub>2.5</sub> concentrations in our study region. However, they might not be the major contributors to fine particle levels. It should be noted that our results are preliminary and might contain a certain degree of bias, since no fire scale and intensity data were incorporated in the analysis. However, in this paper, we primarily attempt to examine the 10 yr spatial and temporal trends of fine particle levels in the region using high spatial resolution PM<sub>2.5</sub> estimates as well as the possible causes for high PM<sub>2.5</sub> concentrations in the south of our domain. Hence, quantification of the contribution of fires to PM<sub>2.5</sub> levels was beyond the scope of this analysis.

### 5 Conclusions

In this paper, we used a two-stage spatiotemporal model incorporating MAIAC AOD data, meteorological fields, and land use variables to estimate PM<sub>2.5</sub> concentrations at 1 km spatial resolution and investigated the 10 yr spatial and temporal trends of PM<sub>2.5</sub> levels in our study region. The results show a reasonable spatial pattern of PM<sub>2.5</sub> levels in the study area as well as in the Atlanta metro area. For instance, high concentrations occur in large urban centers and along major highways, while low concentrations appear in rural and mountainous area. PM<sub>2.5</sub> estimates at high spatial resolutions can provide more details in small geographic regions and reduce exposure misclassification in air pollution and epidemiological studies. The spatial trends of changes in PM<sub>2.5</sub> concentrations indicate that higher pollution reduction occurred in areas with generally higher PM<sub>2.5</sub> levels (e.g. in urban areas and along major highways), while areas with generally lower pollution levels (e.g., in forest and recreational areas) had lower and moderate reduction of fine particle concentrations.
